Comparing SSI In Purse-String Versus Conventional Primary Closure Following Stoma Reversal

Sabih Nofal,¹ Anum Arif,² Ahsan Khan,³ Sundus Saif,⁴ Abdul Waheed Khan,⁵ Muhammad Arif⁶

Abstract

Objective: To compare the frequency of Surgical Site Infection (SSI) and mean length of hospital stay between the Purse-string closure and conventional primary closure techniques for stoma reversal.

Methods: The study was carried out in Surgical Unit-III, Lahore General Hospital Lahore from January 5, 2018 to July 5, 2018. The study designed as an Observational Study. Patients undergoing surgery for Ileostomy were randomly divided into two groups, Group-A (Purse-string closure) and Group-B (Conventional primary closure). All the patients were called for follow up checkup on 14th days after operation and after one month. Both of the groups were checked and recorded for SSI after operation and hospital stay. The data was statistically analyzed by using SPSS v23.01 test (independent sample) used for the comparison of hospital stay mean. Chi-square was also used for the comparison of the frequencies of SSI. Data were stratified for gender and age. A p-value ≤0.05 was considered as significant.

Results: A total of 140 patients were enrolled for this study. Patients were divided into two groups i.e. Group-A (Purse-string closure) and Group-B (Conventional primary closure). In group-A, mean duration of hospital stay was 5.7±1.0 days, while 7.3±1.1 days in group-B, which is statistically significant with a p-value of 0.000. In group-A, surgical site infection was in 4(5.7%) patients, while 11(15.7%) patients of group-B, which is statistically significant with a p-value of 0.046.

Conclusion: The frequency of surgical site infection and mean length of hospital stay after stoma reversal, purse-string suturing technique is significantly less than conventional primary closure technique.

Key Words: Surgical stoma; Ileostomy; Closure; Infection.

Introduction

In colorectal surgery it is properly known that anastomotic leakage is an main problem and complication, specially in coloanal anastomosis and low colorectal. The momentary defunctioning stoma may decrease the re operative rate and anastomotic leakage.¹² The surgery of stoma reversal is generally done when the general conditions of medical recovers in patient. The surgery of stoma reversal might be caused the morbidities and complications like SSI (surgical site infection), postoperative ileus paralytic, bowel obstruction, anastomotic dehiscence and fistulas enterocutaneous.³⁵

The Surgical Site Infection is a very common and important morbidities that wound contamination at site is difficult to preventable. In past CPC (conventional primary closure) technique is the common method that used for the closure of skin in the surgery of stoma reversal with reported results that ranging from 3% to 43%.⁶ SSI after following stoma reversal increase the wound risk of incisional hernia, dehiscence,⁸ health care costs and hospital stay length."
To stop Surgical Site Infection after stoma reversal many techniques used that developed like implementation of gentamycin sponge subcutaneous, iodine wound irrigation, closing of wound by drain tube, late primary closure, secondary closure and string purse closure.\textsuperscript{10,11}

In 1997, Banargee\textsuperscript{12} firstly reported a reliable, simple and cosmetically useful method of skin closure called as PSC (purse string closure). PSC method gives a small opening for the drainage of discharge of wound. This method also heal the wound rapidly than other method of wound healing or wound closure like primary delayed and secondary wound closure techniques.

In a study, it was concluded that, Surgical Site Infection was 36.67\% in primary closure and 10\% in Purse-string closure group.\textsuperscript{13} In another study, it was reported that, Surgical Site Infection occurred in 15.7\% and was more frequent in the Primary Closure group than in the Purse-string closure group 21.4\% vs. 10\%. Time of hospital stay in the Purse-string closure group was shorter than it was in the Primary Closure group (14.79 days vs. 16.44 days).\textsuperscript{14} In another study, it was found that infection occurred in Purse-string closure patients 2.9\% and in Primary Closure patients 21.8\%. Time of hospital stay in the Purse-string closure group was shorter than it was in the Primary Closure group (6.55 days vs. 6.78 days).\textsuperscript{15}

Hypothesis

There is difference in Purse-string closure versus conventional primary closure in terms of less Surgical Site Infection and hospital stay for stoma reversal.

Methods

This Observational Study was conducted in Surgical Unit-III, Lahore General Hospital, Lahore. From January 5, 2018 to July 5, 2018. Patients were sampled via Non probability consecutive sampling. The sample size of 140 (70 in each group) cases was estimated by using 95\% confidence level, 80\% power of test with an expected percentage of surgical site infection in both groups with Purse-string closure 2.9\% and conventional primary closure 21.8\%.\textsuperscript{15}

Surgical Site infection was defined as southampton grade IV and V. Following patients were included in the study 1. Patients of both gender 2. Patients ages between 25-70 3. Patients undergoing surgery for having ileostomy for benign disease of intestine (as per operational definitions).

Following patients were excluded 1. Patients with pre-existing stomal site wound infection 2. Reversal of stoma through laparatomy 3. Post-operative anastomotic leak 4. Uremic patients 5. Patients on chemotherapy and radiations

After taking written informed consent, patients undergoing surgery for ileostomy were randomly divided into two groups by computer generated lottery method, Group-A (Purse-string closure) and Group-B (Conventional primary closure). All operations were done by same surgical team.

In group A and B following method used like in A for the ileostomy reversal circular incision used with stitches of continuous and non-absorbable. The wound of skin was closed by using (Prolene No. 1) that leaving 0.5 cm defect on middle in the skin. In B for the ileostomy conventional incision used. Skin approximately resulting in linear scar.

When these assessments were made the patient were still admitted in hospital. Then all the patients were called for follow up checkup on 14\textsuperscript{th} days after operation and after one month. Both of the groups were checked and record for SSI after operation and hospital stay. All surgeries were done by the same surgical team to reduce bias. All the data and information were collected by proforma. The data was statistically analyzed by using SPSS v23.0. For the quantitative variables like age, hospital stay length mean and standard deviation were calculated. For qualitative variable like gender and SSI the frequency distribution and percentages were calculated. t test (independent sample) used for the comparison of hospital stay mean. Chi-square was also used for the comparison of the frequencies of SSI. Data were stratified for gender and age. Respective tests of significance were applied post stratification. p-value $\leq 0.05$ was considered as significant.

Results

A total of 140 patients were enrolled for this study. Patients were divided into two groups i.e. Group-A (Purse-string closure) and Group-B (Conventional primary closure). In group-A, there were 41(58.6\%) males and 29(41.4\%) females, while in group-B, there were 39(55.7\%) males and 31(44.3\%) females. Mean age of group-A patients was 50.9±14.4 years
and 45.5±12.8 years in group-B. In group-A, 18(25.7%) patients were in 25-40 years age group, while 20(28.6%) and 32(45.7%) were in 41-55 years and >55 years age groups respectively. In group-B, 28(40.0%) patients were in 25-40 years age group, while 25(35.7%) and 17(24.3%) were in 41-55 years and >55 years age groups respectively. In group-A, 26(37.1%) had normal weight, while 23(32.9%) and 21(30.0%) were overweight and obese respectively. In group-B, 21(30.0%) had normal weight, while 24(34.3%) and 25(35.7%) were overweight and obese respectively. In group-A, mean duration of hospital stay was 5.7±1.0 days, while 7.3±1.1days in group-B, which is statistically significant with a p-value of 0.000. In group-A, surgical site infection was in 4(5.7%) patients, while 11(15.7%) patients of group-B, which is statistically significant with a p-value of 0.046.

Discussion

In this study significant results were found that a lower rate of SSI linked with PSC (purse string closure) when compared with CPC (conventional primary closure (CPC)) (5.7% vs. 15.7%, P = 0.046). Our study results matched with two other recent studies that were also small and randomized controlled trials.\(^{16-17}\) Compared the PSC and CPC after stoma reversal. Reid et al. randomly allotted 61 ileostomy patients to either CPC and PSC and found a significant lower rate in Surgical Site Infection than PSC group (6.7% vs. 38.7%, P = 0.005).\(^{18}\) The estimated sample size of study was 60 patients and 66 was enrolled. The trial halted due to the overwhelming number in SSI than CPC group. Camacho-Mauries et al.\(^{16}\) assigned randomly 61 patients with colostomies or ileostomies to CPC or PSC group. They find nill SSIs in PSC group as compared with other group with 36.6% SSI rate in the CPC group (P < 0.0001).\(^{17}\)

The estimated sample size or the rates of SSI were not reported that used in the calculations. Surgical Site Infection rates in CPC group for both above mentioned studies were reported highest for this technique.\(^{19}\)

In present study the rate of Surgical Site Infection i.e. 15.7% in CPC group lies in middle range of previous studies reports\(^{18,20-21}\) with proper sample size and analysis of multivariate to handle potential confounders. Our study also confirms the SSI rate in stoma site is more in CPC group than PSC group. Our results may be generalizable for all patients who undergo colostomy reversals or ileostomy.

The data of this study also matched with previously mentioned studies that includes controlled randomized trials also as other retrospective reviews and case control studies.\(^{22-23}\)

In our study, all stoma Surgical Site Infection were managed bedside by opening the incision to allow the drainage of fluid. No stoma Surgical Site Infection needs antibiotic therapy additionally and reoperation. Similarly results are also find by Vermulst et al.\(^{24}\) in a study that all are manageable easily.

The biological process of wound healing consists of a series of complex interactions between cells, cytokines, and the extracellular matrix. Sometimes, the healing time is relatively long due to seroma formation. The small orifice in the center of the wound allowed self drainage in the PSC group, so wound healing occurred more quickly due to less seroma formation. Murray et al.\(^{25}\) compared the patients of CPC with the patients of open wound retrospectively and find no increase in incisional hernias, hospital stay, fistula formation in between these two groups like SSI rate 36% in CL group.

In these and also in our study the follow up length not properly exclude the increasing incidence of hernias incisional that is known as SSI late complication. In a study, it was concluded that, SSI was 36.67% in primary closure and 10% in Purse-string closure group.\(^{13}\)

In another study, it was reported that, Surgical Site Infection occurred in 15.7% and was more frequent in the Primary Closure group than in the Purse-string closure group 21.4% vs. 10%. Time of hospital stay in the Purse-string closure group was shorter than it was in the Primary Closure group (14.79 days vs. 16.44 days).\(^{14}\)

In another study, it was found that, infection occurred in Purse-string closure patients 2.9% and in Primary Closure patients 21.8%. Time of hospital stay in the Purse-string closure group was shorter than it was in the Primary Closure group (6.55 days vs. 6.78 days).\(^{15}\)

Conclusion

The frequency of surgical site infection and mean length of hospital stay after stoma reversal, purse-string suturing technique is significantly less than
